# Abstract

12

13	The capacity to form endospores is unique to certain members of the low-G+C group of Gram-
14	positive bacteria (Firmicutes) and requires signature sporulation genes that are highly conserved
15	across members of distantly related genera, such as Clostridium and Bacillus. Using gene
16	conservation among endospore-forming bacteria, we identified eight previously uncharacterized
17	genes that are enriched among endospore-forming species. Expression of five of these genes was
18	dependent on sporulation-specific transcription factors. Mutants of none of the genes exhibited a
19	conspicuous defect in sporulation, but mutants of two, ylxY and ylyA, were outcompeted by a
20	wild type strain under sporulation-inducing conditions but not during growth. In contrast, a ylmC
21	mutant displayed a slight competitive advantage over the wild type specific to sporulation-
22	inducing conditions. The phenotype of a ylyA mutant was ascribed to a defect in spore
23	germination efficiency. This work demonstrates the power of combining phylogenetic profiling
24	with reverse genetics and gene regulatory studies to identify unrecognized genes that contribute
25	to a conserved developmental process.

The formation of endospores is a distinctive developmental process wherein a dormant cell type (the endospore) is formed inside of another cell (the mother cell) and ultimately released into the environment by lysis of the mother cell (29, 38). Endospores are metabolically inactive and highly resistant to environmental stresses, such as heat, radiation, chemicals and desiccation (34). At the same time, these spores monitor the environment and are capable of rapidly resuming growth when conditions are favorable (33). Endospore formation is unique to the low-G+C group of Gram-positive bacteria (*Firmicutes*). For the most part, it is restricted to the family Bacillaceae and the class Clostridia, but members of the less well-studied family Veillonellaceae (e.g. Acetonema longum (21, 39)) also produce endospores. The last common ancestor of Clostridium and Bacillus predates the initial rise of oxygen in the atmosphere (3), approximately 2.3 billion years ago. And yet, remarkably, orthologs of signature sporulation genes are shared between the genomes of these distantly related bacteria (17, 38). We wondered whether gene conservation among endospore-formers could be exploited to discover previously unrecognized genes involved in sporulation. Sporulation has been most extensively studied in the model organism B. subtilis. Entry into sporulation is governed by the master regulator Spo0A, which is activated by phosphorylation through a multicomponent signal transduction pathway (19). Spo0A~P directly regulates (activates or represses) the expression of 121 genes (26) and significantly influences the expression of over 500 genes (12). Sporulation is initiated when Spo0A~P levels reach a threshold (14). Sporulating cells undergo several, successive morphological changes, a hallmark

of which is the formation of a two-compartment sporangium consisting of forespore and mother-

cell compartments. As development proceeds, the forespore is wholly engulfed by the mother

cell to create a cell-within-a-cell. The inner cell becomes the dormant spore and is released from the mother cell by lysis (38). Upon release, the mature spore can remain dormant for long periods of time or in response to germinants give rise to a vegetative cell. The developmental program of sporulation is governed in part by the successive action of four compartment-specific sigma factors (appearing in the order  $\sigma^F$ ,  $\sigma^E$ ,  $\sigma^G$  and  $\sigma^K$ ), whose activities are confined to the forespore ( $\sigma^F$  and  $\sigma^G$ ) or the mother cell ( $\sigma^E$  and  $\sigma^K$ ) (24).

Traditional approaches of forward genetics have identified many, if not all, genes that are essential for sporulation (*spo*). These approaches rely on conspicuous phenotypes for the identification of target genes. Complementary approaches, such as the identification of sporulation-specific proteins (e.g. SASP and coat proteins) and transcriptome analysis (11, 40), revealed additional genes under sporulation control, including genes that contribute to efficient sporulation and spore resistance properties. Here we report the application of phylogenetic profiling in an effort to discover additional genes involved in sporulation that might have gone undetected in previous approaches. We therefore sought to identify previously unrecognized genes involved in sporulation in *B. subtilis* on the basis of their conservation among endosporeforming bacteria. Using phylogenetic profile analysis for the initial identification, and transcriptional and mutational analyses, we discovered previously overlooked genes under sporulation control, including two genes, mutants of which caused a small but detectable developmental defect.

#### **Materials and Methods**

Bacterial strains, culturing conditions

71	Escherichia coli strain DH5α was used for propagating plasmids and grown and transformed
72	using standard procedures (31). The <i>B. subtilis</i> strains used in this work are listed in Table 1. All
73	strains were derived from the prototrophic laboratory strain PY79 (45). Transformation of
74	Bacillus strains with double-stranded PCR fragments, plasmid or genomic DNA was done as
75	previously described (42). Sporulation was induced by exhaustion in Difco sporulation (DS)
76	medium, or, in the case of $\beta$ -galactosidase activity assays (see below), by resuspension in
77	Sterlini-Mandelstam (SM) medium (27).
78	
79	Plasmid construction
80	Oligonucleotides used for polymerase chain reaction (PCR) in this study are listed in Table 2.
81	Fragments of the upstream regions of candidate genes, including the respective ribosome binding
82	sites (RBS) and start codons, were amplified by PCR and cloned into pAH124 (6) using the
83	appropriate restriction sites (Table 2). In this way, <i>lacZ</i> reporter constructs were obtained with
84	the start codon of the gene fused directly to the <i>lacZ</i> gene. Constructs were introduced into PY79
85	by transformation.
86	Complementation constructs for the ylmC, ylxY and ylyA mutants were made by PCR
87	amplification of fragments carrying the gene promoters and entire the open reading frames
88	(ORF). These PCR fragments were cloned using the appropriate restriction enzymes into
89	pDG1662 (18), in the case of ylmC and ylxY, or pSac-Cam (25), in the case of ylyA. Constructs
90	were introduced into the respective mutant strains by transformation.
91	
92	Phylogenetic profile analysis

93	For each predicted gene product in <i>B. subtilis subsp. subtilis</i> 168, its presence or absence in 626		
94	complete archaeal and bacterial genomes that were available at the time of the initial		
95	phylogenetic analysis was determined by asking whether a putative ortholog was present (1) or		
96	absent (0) in that species, similar to previously described (44). This analysis included 46		
97	genomes of endospore-forming bacteria belonging to the family Bacillaceae and the class		
98	Clostridia, namely: Bacillus amyloliquefaciens FZB42, Bacillus anthracis str. Ames, Bacillus		
99	anthracis str. 'Ames Ancestor', Bacillus anthracis str. Sterne, Bacillus cereus ATCC 10987,		
100	Bacillus cereus ATCC 14579, Bacillus cereus E33L, Bacillus cereus subsp. cytotoxis NVH 391-		
101	98, Bacillus clausii KSM-K16, Bacillus halodurans C-125, Bacillus licheniformis ATCC 14580,		
102	Bacillus pumilus SAFR-032, Bacillus thuringiensis serovar konkukian str. 97-27, Bacillus		
103	thuringiensis str. Al Hakam, Bacillus weihenstephanensis KBAB4, Geobacillus kaustophilus		
104	HTA426, Geobacillus thermodenitrificans NG80-2, Oceanobacillus iheyensis HTE831,		
105	Alkaliphilus metalliredigens QYMF, Alkaliphilus oremlandii OhILAs, Caldicellulosiruptor		
106	saccharolyticus DSM 8903, Carboxydothermus hydrogenoformans Z-2901, Clostridium		
107	acetobutylicum ATCC 824, Clostridium beijerinckii NCIMB 8052, Clostridium botulinum A str.		
108	ATCC 3502, Clostridium botulinum A str. ATCC 19397, Clostridium botulinum A str. Hall,		
109	Clostridium botulinum F str. Langeland, Clostridium difficile 630, Clostridium kluyveri DSM		
110	555, Clostridium perfringens ATCC 13124, Clostridium perfringens SM101, Clostridium		
111	perfringens str. 13, Clostridium phytofermentans ISDg, Clostridium tetani E88, Clostridium		
112	thermocellum ATCC 27405, Desulfitobacterium hafniense Y51, Desulfotomaculum reducens		
113	MI-1, Moorella thermoacetica ATCC 39073, Symbiobacterium thermophilum IAM 14863,		
114	Syntrophomonas wolfei subsp. wolfei str. Goettingen, Thermoanaerobacter pseudethanolicus		
115	ATCC 33223, Thermoanaerobacter tengcongensis MB4, Pelotomaculum thermopropionicum SI,		

116 Thermoanaerobacter sp. X514. Proteins were then grouped by their distribution patterns across 117 species. In this way, a set of 58 genes, many of which are signature sporulation genes (see 118 below) and all of which are highly enriched among endospore-forming species, was obtained. 119 120  $\beta$ -galactosidase activity assays 121 Samples were collected from shaking cultures in duplicate at various time points after 122 sporulation was induced by resuspension into SM medium. β-galactosidase activity was measured in a Synergy 2 plate reader (BioTek) as previously described (6). The experiment was 123 repeated to ensure reproducibility. β-galactosidase activity is reported in arbitrary (AU) units as 124 125 the rate of ONPG conversion (i.e. V<sub>max</sub>, with units of OD<sub>420</sub> per minute) divided by the OD<sub>600</sub> of 126 the sample at the time of collection, as previously described (6). 127 128 Competition experiments 129 A wild type reference strain was competed against strains mutant for candidate genes as previously described (32), with a few differences. Typically, starting from overnight LB cultures 130 the wild type reference strain (RL5360), which carried an isopropyl β-D-1-thiogalactopyranoside 131 (IPTG)-inducible lacZ, was mixed with an excess mutant strain in 5 ml DS medium. In 132 133 competition assays using ylmC mutants, which displayed an advantage under sporulation-134 inducing conditions, we started with an excess of the wild type strain. Cultures were grown and allowed to sporulate at 37°C in DS medium for 24 hours. Cultures were then heat-treated at 80°C 135 136 for 20 minutes, briefly cooled at room temperature, and diluted in 5ml fresh DS medium. At

appropriate intervals, dilutions were plated on agar plates containing 0.008% w/v 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal) and 1 mM IPTG. Numbers of blue and white colonies were counted, reflecting the ratio of wild type reference to mutant strain, respectively. Similar competition experiments were done in LB to establish if observed phenotypes were specific to sporulation-inducing conditions. In these experiments, we grew the co-cultures at 25°C to minimize the time the culture was in stationary phase. In short, wild type reference and mutant strains were grown at 25°C in LB for 24 hours, and subsequently diluted in 5ml fresh LB for another round of growth. The heat-treatment step was omitted in these experiments.

### Germination of purified spores

Spores were essentially purified as previously described (27). In short, strains were induced to sporulate by growing in DS medium for 48-72 hours. Cells were pelleted by centrifugation, and the pellet was resuspended in ice-cold water. The cells were washed twice with ice-cold water and stored overnight at 4°C. The next day, cells were pelleted by centrifugation and washed another 6-8 times with ice-cold water. In this way, preparation were obtained that were more than 95% phase-bright spores, as judged by phase-contrast microscopy.

For germination assays, spores at an  $OD_{600}$  of 10 were activated by heat-treatment at  $80^{\circ}$ C for 20 minutes and cooled on ice for 2 minutes. Activated spores were germinated at an  $OD_{600}$  of 0.5 in LB medium. Germination was recorded as a loss of optical density in a Synergy 2 plate reader (BioTekin).

We used phylogenetic profile analysis to search for genes in the genome of B. subtilis subsp. subtilis 168 (hereafter simply referred to as B. subtilis) that are specifically conserved among endospore-forming, low-G+C Gram-positive bacteria. A similar method was previously used to identify signature sporulation genes in the thermophilic firmicute Carboxydothermus hydrogenoformans (44). Phylogenetic profiling works by grouping genes according to their distribution patterns in different species. For each predicted gene product in B. subtilis, its presence or absence in all complete archaeal and bacterial genomes available at the time of this analysis (626 genomes in total) was determined by asking whether an ortholog was present in that species. This analysis included 46 genomes of endospore-forming bacteria belonging to the family Bacillaceae and the class Clostridia. Orthologs were then grouped by their distribution patterns across species. In this way, 58 genes were identified that were highly and specifically conserved among endospore-forming bacteria (Fig S1). Many of these are signature sporulation genes with well-studied roles in spore formation, such as spoIIR and spoIIGA, which mediate the activation of the mother-cell-specific transcription factor  $\sigma^{E}$  (20), spoIID, spoIIM and spoIIP, required for forespore engulfment by the mother cell (8, 13, 36), and spoIVA, which encodes a morphogenetic protein required for coat assembly (30). Five genes (i.e. bkdR, ylmC, ymxH, ylzA (formerly designated remA) and ymfB (formerly designated tepA)), however, had no previously documented role in spore formation, and an additional three genes (i.e. ylxY, yteA and ylyA) had previously been shown to be under sporulation control, but no roles in sporulation had been described (10, 40). We hypothesized that these genes might play previously unrecognized or overlooked roles in sporulation.

Six of the eight genes were widely conserved among the 46 endospore-forming *Bacillaceae* and *Clostridia* genomes examined. In the cases of *ymxH* and *ylyA*, however, only 25 and 11 orthologs, respectively, were identified. *ymxH* orthologs are present in almost all endospore-forming *Bacillaceae* species but missing from the majority of endospore-forming *Clostridia* species. Nonetheless, *ymxH* exhibits significant sequence similarity to one of the other genes on our list *ylmC*, which is abundant among endospore-forming bacteria. Meanwhile, a close look at *ylyA*, which is homologous to *yteA*, revealed that several genes identified as *yteA* orthologs in endospore-forming bacteria share similar gene synteny with *B. subtilis ylyA*. *B. subtilis ylyA* is flanked by several well-characterized genes, including, but not restricted to: *divIVA*, encoding a cell division protein, *ileS*, encoding a isoleucyl-tRNA synthetase, *lspA*, encoding a type II signal peptidase, and *rluD*, encoding a pseudouridylate synthase, many of which are found in the vicinity of *ylyA* orthologs in *Bacillaceae* and *Clostridia*. This suggests that these genes are actually *ylyA* orthologs, raising the number of orthologs to 29 (Table 3). Thus, all eight genes are widely conserved among endospore-forming bacteria or are homologous to genes that are.

Finally, two additional genes were identified, yvjA and buk, that had orthologs both in endospore-forming bacteria and in all four species of *Listeria* included in this analysis (Fig S1). *Listeria* species are closely related to *B. subtilis* but do not form spores and lack almost all signature sporulation genes (37). Because of their presence in non-endospore-forming bacteria, we considered yvjA and buk as unlikely candidates for unrecognized sporulation genes.

Nonetheless, and as a control, we retained one of these genes, buk, in our analysis. Thus, a total of nine genes were carried forward for further investigation.

Transcription under sporulation-inducing conditions

We next asked if the nine candidate genes are transcribed under conditions that induce sporulation. For this purpose we built transcriptional reporter constructs, typically cloning a 300-400 base pair fragment directly upstream of the gene and fusing its start codon to that of the lacZ gene. In the case of buk, which is the third gene in a seven-gene (bkd) operon that is involved in branched-chain amino acid utilization (9), we instead cloned an approximately 300 base pair fragment upstream of ptb, the first gene of the operon. B. subtilis strains carrying these constructs integrated at the amyE locus were induced to sporulate by resuspension in SM medium (27), and samples taken at various times were analyzed for  $\beta$ -galactosidase activity. Seven of the nine reporters were expressed during sporulation, six of which were induced at various times after the induction of sporulation (Fig 1). We did not observe activity for the bkdR and ylzA reporters under the tested conditions (data not shown).

The bkd reporter was active from the time of the induction of sporulation, decreasing only slightly during the time it was monitored (Fig 1A). As previously reported, expression of the bkd operon depends on the alternative sigma factor  $\sigma^L$  and BkdR (9). Indeed, in a bkdR mutant expression was abolished (Fig 1A). We next measured expression in a strain mutant for spo0A. The spo0A gene encodes the master regulator for entry into sporulation Spo0A, which is active in its phosphorylated form Spo0A~P (19, 38). Activity was approximately two-fold higher compared to wild type at the times tested. Interestingly, in a strain doubly mutant for spo0A and bkdR expression levels were similar to that of wild type (Fig 1A), showing that in the absence of Spo0A BkdR is not required for expression. That is, a spo0A mutation is epistatic to a bkdR mutation. This suggests that BkdR antagonizes Spo0A~P to activate transcription from the bkd operon promoter. We found a potential Spo0A binding site (GTCGAAA; Fig S2), with high

similarity to the consensus binding sequence (TTTGTCGAAA (26)), located immediately downstream to the  $\sigma^L$ -dependent transcriptional start site (9). Just upstream of the promoter are tandem sequences previously shown to be important for BkdR-mediated activation (9). *In toto*, these observations suggest that the binding of BkdR upstream of the promoter overcomes the repressive effect of the binding of Spo0A~P just downstream of the start site.

The ymxH reporter was expressed from an early time, increasing slightly but constantly during the first five hours (Fig 1B). We tested the activity in strains mutant for spo0A and sigF, which encodes the first forespore-specific sigma factor  $\sigma^F$  (38). Expression in a spo0A mutant was up-regulated, steadily increasing from one hour after sporulation was induced. In contrast, activity in a sigF mutant was unchanged compared to wild type (Fig 1B). These findings suggest that ymxH is directly or indirectly under the negative control of Spo0A~P but is not otherwise under sporulation control.

Expression from the ylxY and ylmC reporters was induced between hour one and two of sporulation (Fig 1C, D). Previous work indicated that ylxY expression is  $\sigma^E$ -dependent and under the negative control of the mother cell-specific regulator SpoIIID (10-11). We tested the activity of the ylxY and ylmC reporters in strains mutant for sigF, sigE, which encodes the mother cell-specific sigma factor  $\sigma^E$ , or sigG, which encodes the late-appearing, forespore-specific sigma factor  $\sigma^G$ . Activity for both was abolished in the sigF and sigE mutants, but reached wild type levels in the sigG mutant (Fig 1C, D). Thus, these genes are transcribed in a  $\sigma^E$ -dependent manner.

Finally, three reporters were induced between two and three hours after sporulation was induced, namely those for *ymfB*, *yteA* and *ylyA* (Fig 1E-G). Previous transcriptome analyses

indicated that yteA and ylyA are indeed part of the  $\sigma^G$  regulon (40), whereas ymfB was not known to be under sporulation control. The activity of all three reporters was abolished in a sigG mutant (Fig 1E-G). In addition, ylyA was previously shown to be under the control of SpoVT, a modulator of  $\sigma^G$ -dependent transcription (2, 40). We tested the activity of all three reporters in a strain mutant for spoVT. The activity of the yteA and ylyA reporters was markedly reduced in a spoVT mutant, whereas the activity of ymfB reporter increased in a spoVT mutant (Fig 1E-G).

In summary, we conclude that five of the nine genes in our investigation are under sporulation control with two, namely ylxY and ylmC, being under the control of  $\sigma^E$  and three, ymfB, yteA and ylyA, under the control of  $\sigma^G$ .

Competition-based analysis of candidate gene mutants

We constructed mutant strains for eight of the nine genes by deleting and replacing their ORF with antibiotic-resistance cassettes. We were unable to obtain a mutant for the ninth gene *ylzA*. Previously, others obtained transposon insertions directly upstream of *ylzA*; however, no report was made of transposon insertions internal to the *ylzA* coding sequence (43).

None of the eight mutants had a conspicuous phenotype as judged by colony morphology or spore formation (data not shown). Thus, if any of these genes represent previously uncharacterized sporulation genes, their contribution to spore formation must be subtle. To test for such a subtle role, we carried out competition experiments in which mutant strains were competed for several rounds of sporulation against a wild type reference strain marked by an IPTG-inducible *lacZ* gene. Typically, mutant cells were several fold in excess to the wild type at

the start of the experiment. Co-cultures of the mutant and wild type were grown and allowed to sporulate at 37°C in DS medium for 24 hours. The culture was then heat-treated at 80°C and diluted in fresh DS medium for another round of sporulation. At appropriate intervals, dilutions were plated on agar plates containing X-gal and IPTG and blue (wild type) and white (mutant) colonies were counted. Mutant strains that were out competed (or in one case slightly under competed) by the wild type were next subjected to competition experiments in growth medium to determine if the observed competition phenotype was an indirect consequence of a growth defect rather than a defect in sporulation. In these experiments, co-cultures were grown at 25°C in LB medium for 24 hours and subsequently diluted in fresh LB medium for another round of growth. The heat-treatment step was omitted in these experiments.

The mutant strains fell into three categories: those that did not have a competition phenotype under sporulation-inducing conditions; those that had a phenotype under sporulation-inducing but not under growth conditions; and lastly, those that had a phenotype under both conditions. The first category comprised the *bkdR*, *ymxH*, *ymfB* and *yteA* mutants. In a competition experiment in which the wild type reference strain was competed against an unmarked wild type strain the percentage of the wild type reference strain remained constant during several rounds of competition (Fig S3), indicating that the inducible *lacZ* construct did not affect the fitness of the reference strain. Similarly, in competition experiments with strains mutant for *bkdR*, *ymxH*, *ymfB* or *yteA* the percentage of the wild type reference strain remained constant (Fig S3).

The second category comprised the ylxY, ylyA and ylmC mutants. Strains mutant for ylxY and ylyA had clear competition deficits under sporulation-inducing conditions. Over the course of nine and five rounds of competition, respectively, the percentage of wild type reference strain

had increased from approximately 20% to 90% of the population (Fig 2, 3). Genetic complementation by reintroducing a copy of the respective gene at an ectopic locus restored competitiveness to the mutant strains (Fig 2, 3), confirming that the observed phenotypes resulted from deletion of the genes. In contrast to the apparent deficit of *ylxY* and *ylyA* mutants, the *ylmC* mutant exhibited a slight competitive advantage under sporulation-inducing conditions (Fig 4). As before, genetic complementation by reintroducing a copy of *ylmC* at the ectopic *amyE* locus reversed this phenotype (Fig 4). All three competition phenotypes were found to be specific to competition experiments under sporulation-inducing conditions, because no changes from the starting ratio were observed in competition experiments during growth (Fig 5).

Finally, the third category contained only one strain, the *buk* mutant, which had a clear competition deficit under sporulation-inducing and growth conditions (Fig S4).

## A ylyA mutant is defective in germination

We do not know the precise step in sporulation at which the ylxY mutation impedes spore formation or the step at which the ylmC mutation confers a competitive advantage. However, in the case of ylyA, we can, at least in part, attribute the competitive disadvantage to impaired spore germination. As shown in Fig. 6, spores from a ylyA mutant are slower to germinate than either the wild type parent or a ylyA mutant strain harboring a wild type copy of the gene at the ectopic sacA locus.

### Discussion

Using phylogenetic profiling, we identified eight genes (*i.e. bkdR*, *ylmC*, *ymxH*, *ylxY*, *ylzA*, *ymfB*, *yteA* and *ylyA*) that are widely conserved among endospore-forming species of *Bacillaceae* and *Clostridia*, but were not previously reported to be involved in sporulation or, in the case of ylxY, yteA and ylyA, not well characterized. ymfB, which is homologous to ClpP-like proteases (Table 3), was previously suggested to be involved in translocation and processing of the  $\alpha$ -amylase AmyQ ((4); ymfB was therein named tepA). Researchers from the same laboratory, however, later reported that they were unable to replicate the initial results with a clean knockout of ymfB (41). ylzA, which encodes a hypothetical protein with no clear homology to known proteins (Table 3), was previously shown to be involved in the regulation of extracellular matrix components during biofilm formation in B.subtilis ((43); ylzA is therein designated remA). Five of the eight genes were found to be under the control of sporulation-specific transcription factors, with ylmC and ylxY being under the control of the mother cell-specific sigma factor  $\sigma^E$ , and ymfB, yteA and ylyA under the control of the forespore-specific factors  $\sigma^G$  and SpoVT.

Inactivation of ylxY, ylyA and ylmC, resulted in measurable changes in competitiveness under sporulation-inducing conditions, but not under growth conditions.

We included buk as a control in our investigation. Like the eight other genes, orthologs of buk are enriched among endospore-forming bacteria but are also found in some non-endospore-forming species, most notably Listeria, a close relative of B. subtilis that is asporogenic. The buk gene, which codes for a butyrate kinase, is part of a seven-gene operon in B. subtilis that is involved in the utilization of branched-chain amino acids as a nitrogen source (9). Orthologs of other members of the operon are widespread among bacteria, much more so than buk itself. In B. subtilis the operon is under the control of the alternative sigma factor  $\sigma^L$  and the transcription activator BkdR (9), which as we have shown is itself highly conserved among endospore-

forming bacteria. Inactivation of *buk* resulted in defects that were not specific to sporulation, and the *bkd* operon promoter was constitutively active under the tested conditions. Interestingly, we found a putative Spo0A binding site adjacent to the predicted transcriptional start site, and our results indicate that BkdR antagonizes Spo0A~P to activate expression. The presence of BkdR orthologs in almost all endospore-forming species analyzed (Table 3), but not *Listeria* species, supports the idea that BkdR is conserved among endospore-forming bacteria to counteract the effect of Spo0A~P on transcription.

ylmC and ymxH are paralogs that code for small hypothetical proteins that resemble a motif known as photosynthetic reaction center (PRC) beta-barrel domain (Table 3). The PRC domain, which is itself widespread among photosynthetic and non-photosynthetic bacteria, archaea and plants, is thought to mediate protein-protein interactions (1). Deletion of ylmC resulted in a strain that had a slight competitive advantage over the wild type under sporulation-inducing conditions. It is unclear what causes this unexpected phenotype. A double mutant of ylmC and ymxH essentially had the same phenotype as the ylmC single mutant (data not shown). We infer that YlmC must confer some fitness advantage during spore formation under unknown environmental conditions (e.g. a spore resistance property) but that production of the protein evidently imposes a slight cost on spore formation that impedes development.

Deletion of ylxY and ylyA resulted in clear competitive deficits specific to sporulation-inducing conditions. ylxY encodes a probable polysaccharide deacetylase (Table 3), and exhibits some similarity to two B. subtilis genes under sporulation control, namely pdaA and pdaB, mutants of which display defects in spore cortex maturation (15-16, 35). The nature of the competition deficit of the ylxY mutant is currently unknown. In contrast, we have determined that the competition defect of the ylyA mutant stems not from a defect in spore formation  $per\ se$  but

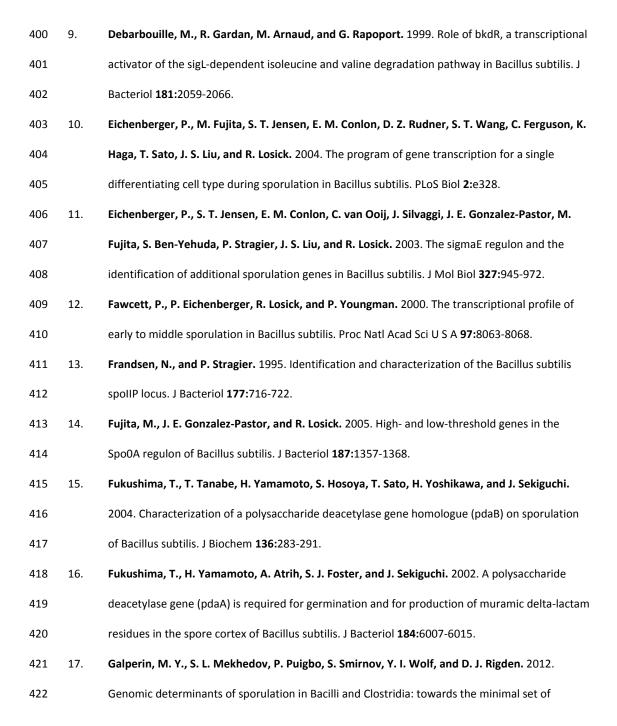

rather from impaired germination of the mutant spores. Gourse and co-workers previously reported that YlyA and YteA share some sequence similarity to the transcription factor DksA (23). DksA inhibits the transcription of ribosomal RNA (rRNA) genes by direct interaction with RNA polymerase (28). Mutation of *ylyA* or *yteA*, however, seemingly did not affect the activity of the P1 promoter of the rRNA gene *rrnB* under any of the tested growth conditions (23). It will be interesting to see whether YlyA similarly modifies RNA polymerase activity and if so whether this modification influences the expression of genes involved in spore germination.

Our results reinforce the view that phylogenetic profiling in combination with reverse genetics and gene regulatory studies can be a powerful tool for the discovery of genes that play a subtle role in a complex developmental process and whose contributions might otherwise be overlooked by traditional approaches of forward genetics.

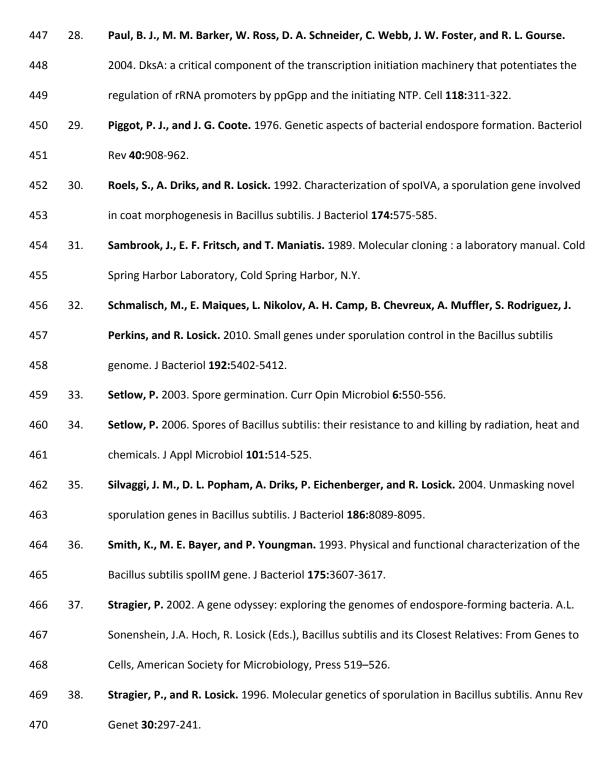

#### Acknowledgments

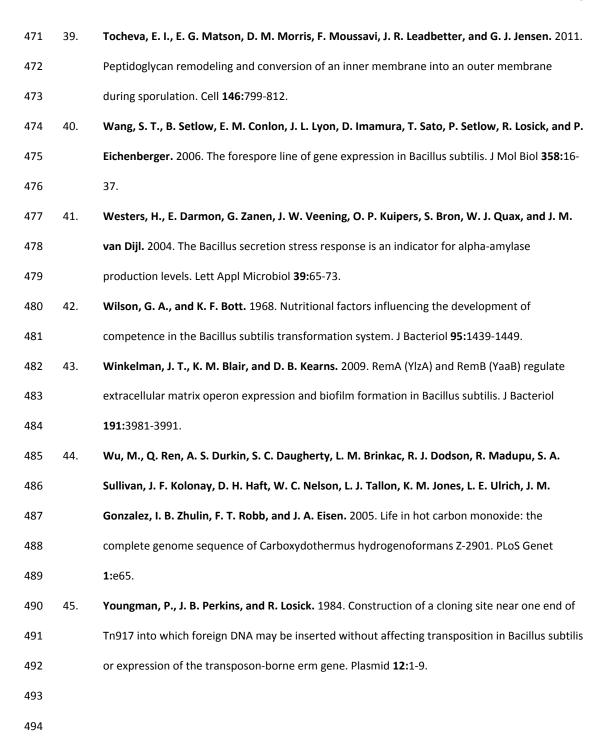

We thank Martin Wu for help with phylogenetic profiling, and Rick Gourse for bringing to our attention the similarity of *yteA* and *ylyA* to *dksA*. We thank members of the Losick laboratory for helpful discussion. 495 Figure legends 496 Figure 1. Transcription and regulatory gene-dependence of candidate sporulation genes. 497 498 Strains carrying lacZ transcriptional reporter constructs for bkd (operon including buk; A), ymxH (B), ylxY(C), ylmC(D), ymfB(E), yteA(F) and ylyA(G) were induced to sporulate and  $\beta$ -499 500 galactosidase activity was monitored for samples taken at indicated time points after sporulation-501 induction. Activity (AU) was assayed in wild type ( $\square$ ) or strains mutant for spo0A ( $\times$ ), sigF ( $\Diamond$ ), 502  $sigE(\circ)$ ,  $sigG(\Delta)$ ,  $spoVT(\bullet)$ , bkdR(+) or spo0A and bkdR(\*). 503 Figure 2. A ylxY mutant exhibits a competition deficit under sporulation-inducing 504 conditions. A wild type reference strain carrying an IPTG-inducible *lacZ* gene (RL5360) was 505 506 competed in DS medium against a ylxY mutant, starting with approximately 20% wild type 507 strain. Cultures were incubated at 37°C for 24 hours, heat-treated at 80°C, and diluted in fresh 508 DS medium. After indicated rounds of competition, dilutions of the culture were plated on agar 509 plates containing IPTG and X-gal, and blue (wild type) and white (mutant) colonies were counted. Bar graphs indicate the percentage of the wild type reference strain. The wild type strain 510 was competed against a ylxY mutant (dark grey), and a complemented strain carrying a copy of 511 512 *ylxY* at the ectopic *amyE* locus (light grey). 513

Figure 3. A ylyA mutant exhibits a competition deficit under sporulation-inducing

conditions. A wild type reference strain carrying an IPTG-inducible *lacZ* gene (RL5360) was

competed in DS medium against a *ylyA* mutant, starting with approximately 20% wild type strain. Cultures were incubated at 37°C for 24 hours, heat-treated at 80°C, and diluted in fresh DS medium. After indicated rounds of competition, dilutions of the culture were plated on agar plates containing IPTG and X-gal, and blue (wild type) and white (mutant) colonies were counted. Bar graphs indicate the percentage of the wild type reference strain. The wild type strain was competed against a *ylyA* mutant (dark grey), and a complemented strain carrying a copy of *ylyA* at the ectopic *sacA* locus (light grey).

Figure 4. A ylmC mutant exhibits a slight competitive advantage under sporulation-inducing conditions. A wild type reference strain carrying an IPTG-inducible lacZ gene (RL5360) was competed in DS medium against a ylmC mutant, starting with approximately 75% wild type strain. Cultures were incubated at 37°C for 24 hours, heat-treated at 80°C, and diluted in fresh DS medium. After indicated rounds of competition, dilutions of the culture were plated on agar plates containing IPTG and X-gal, and blue (wild type) and white (mutant) colonies were counted. Bar graphs indicate the percentage of the wild type reference strain. The wild type strain was competed against a ylmC mutant (dark grey), and a complemented strain carrying a copy of ylmC at the ectopic amyE locus (light grey).

Figure 5. ylxY, ylyA and ylmC mutants do not exhibit a significant competitive deficit during growth. A wild type reference strain carrying an IPTG-inducible lacZ gene (RL5360) was competed in LB medium against an unmarked wild type (dark grey), and strains mutant for ylxY (light grey), ylyA (black), and ylmC (white), starting with approximately 20% wild type

538 strain. Cultures were incubated at 25°C for 24 hours, and diluted in fresh LB. After indicated 539 rounds of competition, dilutions of the culture were plated on agar plates containing IPTG and X-gal, and blue and white colonies were counted. Bar graphs indicate the percentage of the wild 540 541 type reference strain. 542 543 Figure 6. A ylyA mutant is delayed in germination. Purified spores were heat-treated and cooled on ice. Activated spores were germinated at an  $OD_{600}$  of 0.5 by dilution in LB medium. 544 Every 4 minutes after germination-induction the OD<sub>600</sub> was measured, and germination is 545 546 reported as the percentage in the drop in optical density. 547
